Background

Tinnitus is the perception of sound in the absence of an external auditory stimulus; as such, tinnitus is a symptom, not a disease. An estimated 16 percent of the American population (50 million people) experience tinnitus, with up to 16 million seeking medical help and 2 million being unable to lead a normal life.1 The prevalence of tinnitus increases with age and noise exposure.2,3 Additionally, tinnitus is an increasing problem in more recent birth cohorts.4

A variety of conditions and experiences can lead to tinnitus, but the exact physiology is still unknown. Patients are often described as presenting with symptoms of either objective or subjective tinnitus. Objective tinnitus is perceptible by patients and examiners. Subjective tinnitus is perceptible only by patients, yet is not due to a hallucination. Both forms of tinnitus may or may not be idiopathic. Some investigators have argued that tinnitus should be classified by origin, either as somatic or neurophysiologic.5 In this review, we will use the term subjective idiopathic tinnitus, rather than neurophysiologic tinnitus, because it is the term most commonly used in the current literature. Subjective idiopathic tinnitus is also the most commonly diagnosed type of tinnitus.6

Effective Health Care Program

The Effective Health Care Program was initiated in 2005 to provide valid evidence about the comparative effectiveness of different medical interventions. The object is to help consumers, health care providers, and others in making informed choices among treatment alternatives. Through its Comparative Effectiveness Reviews, the program supports systematic appraisals of existing scientific evidence regarding treatments for high-priority health conditions. It also promotes and generates new scientific evidence by identifying gaps in existing scientific evidence and supporting new research. The program puts special emphasis on translating findings into a variety of useful formats for different stakeholders, including consumers.

The full report and this summary are available at www.effectivehealthcare.ahrq.gov/reports/final.cfm.

Treatments for subjective idiopathic tinnitus are wide ranging in scope and may include medical/surgical treatments, sound treatments/technologies, and psychological/behavioral treatments. For the present review, treatment groups revolve around four main categories
of intervention: pharmacological or food supplement, medical/surgical, sound technology, and psychological/behavioral.

Scope and Key Questions

Standardized guidelines for the diagnosis and treatment of tinnitus do not exist in the United States. To help inform medical practice, this systematic review was undertaken to explore prognostic factors and strategies for the optimal management of tinnitus. Three Key Questions (KQs) governed the review:

KQ1. In patients with symptoms of tinnitus (ringing in the ears, whooshing sounds, etc.), what is the comparative effectiveness of methods used to identify patients for further evaluation or treatment?

KQ2. In adults with subjective idiopathic (nonpulsatile) tinnitus, what is the comparative effectiveness (and/or potential harms) of medical/surgical, sound treatment/technological, or psychological/behavioral interventions, including combinations of interventions?

KQ3. For adults with subjective idiopathic tinnitus, what prognostic factors, patient characteristics, and/or symptom characteristics affect final treatment outcomes?

Analytic Framework

Following consultation with Key Informants, the Agency for Healthcare Research and Quality (AHRQ) Task Order Officer, and the investigative team, key research questions were developed. Figure A shows a flow diagram indicating the relationship between research questions in this comparative effectiveness review (CER). This framework depicts the KQ as outlined in the PICOTS (population(s), interventions, comparators, outcomes, timing or followup, and setting) format. The PICOTS components for each KQ are provided in full detail in Table A.

Figure A. Analytic framework

KQ = Key Question

aAny studies that used the terms “annoyance” or “distress” to describe their outcomes were included under the category of “discomfort.”

bThe outcome “severity” was added during data extraction. As severity was an outcome reported in 18 of 34 papers, it was decided that it should not be collapsed into any other outcome category.
Methods

Search Strategy

The search was conducted in six databases—MEDLINE®, Embase®, Cochrane CENTRAL, PsycINFO®, AMED® and CINAHL®—as well as the grey literature, from January 1970 to June 2012. The search strategy used medical subject headings (MeSH®), keywords, and text words, including “tinnitus” and “humans not animals,” with a limit to English-language citations. The search also included the following Web sites: American Tinnitus Association, Association for Research in Otolaryngology, American Academy of Audiology, Emory University Tinnitus and Hyperacusis Center, Tinnitus Research Initiative, and Deafness Research UK. Reference lists of eligible studies were also reviewed at full-text screening.

Criteria for Inclusion/Exclusion of Studies in the Review

Included studies had to be randomized controlled trials (RCTs) or observational studies with true control groups (e.g., cohort, case control). For KQ2 and KQ3, included studies had to evaluate tinnitus treatments. Studies were excluded when tinnitus resulted from middle-ear pathologies (mechanics, otitis media, otosclerosis, etc.), when interventions were stapedectomy or tympanoplasty, or when interventions were focused on determining whether patients had psychosomatic tinnitus. See Table A for inclusion and exclusion criteria.

Data Extraction, Assessment of Risk of Bias, and Applicability

Standardized and validated scales were used (the Newcastle-Ottawa quality assessment scales for case-control studies and cohort studies, and the Jadad scale for RCTs) to assess risk of bias. Two raters evaluated the studies using standardized assessment forms, and disagreements were resolved through consensus. Applicability was assessed by considering comorbidities (psychological or related to hearing loss), ages of subjects, locations where study subjects were recruited, specific treatment providers, and lengths of time to treatment.

Data Synthesis and Strength of Evidence

All included studies were summarized in narrative form and stratified by the different outcomes and interventions. Interventions were organized into four main categories: pharmacological or food supplement, medical, sound technology, and psychological/behavioral. Meta-analysis was not undertaken due to the clinical heterogeneity of the interventions and outcomes; however, standardized mean differences were estimated for each study and presented in forest plots to compare effect sizes across studies. Two reviewers based their assessments of the overall strength of evidence (SOE) on AHRQ’s “Methods Guide for Effectiveness and Comparative Effectiveness Reviews.”

| **Interventions** | **KQ1**: Direct observation or observation of sound with stethoscope; referral to a health professional with expertise on managing tinnitus (i.e., otolaryngologist, audiologist, neurologist, mental health professional); administration of scales/questionnaires to assess severity (THI, TRQ, TSI, VAS, etc.)  
**KQ2**: Any treatment/therapy used to reduce/help cope with tinnitus, including but not limited to the following:  
**Medical/Surgical**  
• Pharmacological treatments:  
  – Tricyclic antidepressants (e.g., amitriptyline, nortriptyline, and trimipramine)  
  – Selective serotonin-reuptake inhibitors: fluoxetine and paroxetine  
  – Other: trazodone; anxiolytics (e.g., alprazolam); vasodilators and vasoactive substances (e.g., prostaglandin E1); intravenous lidocaine; gabapentin; Botox (botulinum toxin type A); and pramipexole)  
• Laser treatments  
• TMJ treatment: dental orthotics and self-care, surgery  
• Transcranial magnetic stimulation  
• Hyperbaric oxygen therapy  
• Complementary and alternative medicine therapies: Gingko biloba extracts; acupuncture; diet, lifestyle, and sleep modifications (caffeine avoidance, exercise)  
**Sound Treatments/Technologies**  
• Hearing aids, cochlear implants, sound generators, maskers  
• Neuromonics  
**Psychological/Behavioral**  
• Cognitive behavioral therapy, biofeedback, education, relaxation therapies, Progressive Tinnitus Management, tinnitus retraining therapy  
**Combination Therapies**  
• Any combination of tinnitus interventions (e.g., pharmacological treatment with cognitive behavioral therapy)  
**KQ3**: Any treatment/therapy used to reduce/help/cope with tinnitus, including but not limited to those described in KQ2 | **KQ1**: Nondirect observations  
**KQ2**: No exclusions for interventions  
**KQ3**: No exclusions for interventions |

| Comparators      | **KQ1**: Different clinical evaluation methods used to characterize a diagnosis and measure severity of subjective idiopathic tinnitus  
**KQ2**: Placebo, no treatment, wait list, treatment as usual, other intervention/treatment with control  
**KQ3**:  
- Prognostic factors: length of time to treatment after onset, audiological factors (degree and type of hearing loss, hyperacusis, loudness tolerance, masking criteria, etc.), head injury, anxiety symptoms, mental health disorders, and duration of tinnitus  
- Patient characteristics: age, sex, race, medical or mental health comorbidities, socioeconomic factors, noise exposure (environmental, recreational, and work related [including active and past military duty, and occupational hazards]), involvement in litigation, third-party coverage  
- Symptom characteristics: origin/presumed etiology of tinnitus, tinnitus duration since onset, subcategory of tinnitus, severity of tinnitus                                                                                                                                                                                                                                                                                                                                                             | **KQ1**: No exclusions  
**KQ2**: No comparator/control  
**KQ3**: No exclusions                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| Outcomes         | **KQ1**: Final outcome: no treatment, need for specialized treatment (e.g., audiology, otolaryngology, neurology, mental health care), extent of intervention  
**KQ2**: Sleep disturbance, discomfort, anxiety symptoms, depression symptoms, subjective loudness, quality of life, tinnitus severity, adverse effects (worsening of tinnitus, sedation, surgical complications)  
**KQ3**: Time until improvement, sleep disturbance, discomfort, anxiety symptoms, depression symptoms, subjective loudness, quality of life, return to “normal” work, adverse effects (worsening of tinnitus, sedation, surgical complications)                                                                                                                                                                                                                     | No exclusions                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| Publication      | English                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | Non-English                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| Publication      | language                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

### Peer Review and Public Comment

Experts in audiology, epidemiology, and medical specialties, and researchers and individuals representing stakeholder and user communities were invited to provide external peer review of this CER. The AHRQ Task Order Officer and an associate editor also provided comments on the report. The draft report was posted on the AHRQ Web site for 4 weeks to elicit public comment. All reviewer comments were considered and the text revised. A disposition-of-comments report will be made available on the AHRQ Web site 3 months after the posting of this final report.

### Results

The initial literature search yielded 9,725 citations; 834 citations (8.6 percent) passed title and abstract screening. From the studies screened at full text, 52 eligible publications were extracted for data. None were eligible for KQ1 or KQ3.

**KQ1. In patients with symptoms of tinnitus (ringing in the ears, whooshing sounds, etc.), what is the comparative effectiveness of methods used to identify patients for further evaluation or treatment?**

No studies were found to address this KQ.

**KQ2. In adults with subjective idiopathic (nonpulsatile) tinnitus, what is the comparative effectiveness (and/or potential harms) of medical/surgical, sound treatment/technological, or psychological/behavioral interventions, including combinations of interventions?**

**Pharmacological or Food Supplement Interventions**

A total of 17 articles reported on 16 unique studies that evaluated interventions in the pharmacological or food supplement domain (Table B). Five articles investigated antidepressant drugs versus placebo. These drugs included sertraline, paroxetine, trazodone, and nortriptyline. Dosage levels in the sertraline, paroxetine, and nortriptyline articles were at the recommended levels for treating depression. However, the dosage level in the trazodone study was below the recommended dose for depression; the dosage level was instead suitable for use as a sleep aid. Five publications examined neurotransmitter drugs, which stimulate or enhance γ-aminobutyric acid (GABA), versus placebo. The neurotransmitter drugs were gabapentin, baclofen, alprazolam, and acamprosate. Three studies investigated other drugs, including methylprednisolone versus placebo, vardenafil versus placebo, and Deanxit versus placebo (with each participant given 1 mg clonazepam in addition to Deanxit or placebo). Four papers evaluated food supplements, with two focused on Gingko biloba, one on zinc, and one on honeybee larvae. All food supplements were compared with placebo (which was hydrogenated dextrin in the larve study). All of the studies were RCTs.

Adverse effects spanned a range of clinical severity, from dry or sour mouth to confusion, but generally subsided after discontinuation of treatment. Four studies reported symptoms of sedation (sleepiness, drowsiness) during the use of antidepressants (trazodone and paroxetine) and neurotransmitter drugs (baclofen, alprazolam). The findings for sedation were inconsistent and imprecise, as estimates of affected patients were poorly characterized; the SOE for sedation was insufficient in patients with tinnitus.

Note: Deanxit comparison is a crossover trial of Deanxit vs. placebo, with each participant given 1 mg clonazepam in addition to Deanxit or placebo; honeybee larvae comparator is hydrogenated dextrin.

### Medical Interventions

Eleven studies were included for medical interventions in KQ2 (Table C). Six29-34 of these evaluated repetitive transcranial magnetic stimulation (rTMS) or electromagnetic stimulation; three evaluated low-level laser therapy (LLLT);35-37 and one each evaluated acupuncture38 and acoustic coordinated reset neuromodulation (ACRN) therapy.39 All the studies in the medical intervention group have small sample sizes (n<60).

Adverse effects were not consistently reported or specified in the methods of the studies. None of the studies in the medical interventions group reported dropouts related to adverse effects. In general, adverse effects were transient and mild.

### Sound Technology Interventions

Five publications (of four studies) evaluated sound technology interventions in head-to-head comparisons (Table D). Interventions included (1) hearing aids versus sound generators; (2) Neuromonics with one stage or two stages of stimulus conditions; (3) information only, information plus relaxation training, information plus long-term low-level white noise (LTWN), and information plus relaxation training plus LTWN; and (4) cognitive behavioral therapy (CBT) with noise generator (NG), CBT alone, tinnitus education (TE) plus NG, and TE with no NG. Each study assessed a different sound technology. For this reason, formal SOE tables for sound technologies were not included in the review. All of the studies evaluating sound technologies were at high risk of bias and consistency was unknown. Small sample sizes led to these studies being considered imprecise. Overall, there is insufficient information to judge the SOE for the studies evaluating sound technologies.

Adverse effects were not consistently reported or specified in the methods of the studies. None of the studies in the sound technology interventions group reported dropouts related to adverse effects. In general, adverse effects were not mentioned in these reports.

</tbody>
</table>
Psychological and Behavioral Interventions

A total of 19 RCTs evaluated interventions in the psychological and behavioral domain (Table E). Ten RCTs compared some form of CBT with an inactive control, and six compared CBT with another treatment. Two trials compared tinnitus retraining therapy (TRT) with an inactive control, and three compared TRT with another treatment. Three RCTs compared some form of relaxation therapy with an inactive control, and one compared relaxation with another treatment. Six studies evaluated some other type of psychological/behavioral therapy compared with an inactive control, and one involved head-to-head comparisons between treatments.

Adverse effects were not consistently reported or specified in the methods of the studies. None of the studies in the psychological and behavioral interventions group reported dropouts related to adverse effects. Eight studies clearly stated there were no adverse effects reported. One study reported an increase in negative effects (loudness of and discomfort from their tinnitus) from intensive self-monitoring.

CBT = cognitive behavioral therapy; TRT = tinnitus retraining therapy; TSQoL = tinnitus-specific quality of life
KQ3. For adults with subjective idiopathic tinnitus, what prognostic factors, patient characteristics, and/or symptom characteristics affect final treatment outcomes?

No studies were found to address this KQ.

Discussion and Conclusions

In adults with subjective idiopathic (nonpulsatile) tinnitus, the comparative effectiveness (and/or potential harms) of medical/surgical, sound treatment/technological, or psychological/behavioral interventions (including combinations of interventions) are summarized below (KQ2). This (CER) demonstrates important research gaps with respect to KQ1 (methods to identify those for further evaluation or treatment) and KQ3 (prognostic factors).

When considering the applicability of study findings in general, the study populations were relatively homogeneous and were limited to predominately middle-aged (≥50 years of age) persons suffering from subjective idiopathic tinnitus of mild to moderate severity. Of course, hearing loss also increases markedly with age starting in the fourth decade, and hearing loss and tinnitus often co-occur. Nevertheless, tinnitus is a problem not only for older adults or for people with clinically significant hearing loss. A recent survey estimated that tinnitus was prevalent in 12.2 percent of the U.S. population under 44 years of age. However, there is little evidence on which to draw conclusions about the efficacy of the therapies in persons younger than 42 years of age. The finding of generational differences suggests that reports of tinnitus tend to increase with more recent birth cohorts compared with earlier birth cohorts. Researchers should explore age and cohort differences as programs to treat, and possibly even programs to prevent, tinnitus continue to be developed and evaluated.

Tinnitus is a chronic condition. The longest followups in the included studies did not exceed 16 weeks in pharmacological and medical supplement categories, the included studies did not provide data on the medium- to long-term effects of the active treatments.

Many of the studies in this review were conducted in Europe, where the professional model of hearing care/audiology is different from that typically seen in the United States. In the United States, the coping/CT oriented interventions fall more within the scope of practice of psychologists than audiologists. If future interventions were to require more of this type of psychological intervention, there would need to be a shift in the training of audiologists or a shift to more team-oriented practice involving both audiologists and psychologists.

In general, drawing overall conclusions about treatment benefits proved challenging due to the diversity of interventions and outcomes in the included studies. Studies were heterogeneous in terms of populations, treatments, treatment modalities, study duration and followup periods, and outcome measures. Some interventions showed positive benefits, but it was difficult to judge the degree of clinical significance of the changes observed. Standardized mean differences were estimated for each study because different outcomes were used; the use of diverse outcomes makes it more difficult to assess clinical significance across studies. Even if differences in treatment-placebo scale scores were statistically significant, these differences may not be clinically meaningful. Future research must consider pilot work to establish the validity of many of the outcomes used in the included studies; moreover, specific adaptations of measures validated in nontinnitus populations (e.g., study-specific visual analog scale) should be established in the tinnitus population, particularly for the attributes of change over time. For some of the tinnitus-specific outcomes, it is critical that clinically important differences be established.

Key Findings and Strength of Evidence

Pharmacological or Food Supplement Interventions

A total of 16 unique studies (17 publications) evaluated the efficacy of pharmacological interventions or food supplements in tinnitus. The included articles evaluated 14 different interventions, all of which were compared with some form of placebo. For the most part, the interventions failed to demonstrate statistically significant effects compared with placebo on any of the outcomes. Various interventions showed statistically significant effects on some outcomes: nortriptyline and...
honeybee larvae\textsuperscript{28} for depression; alprazolam\textsuperscript{19} and zinc\textsuperscript{27} for loudness; and acamprosate\textsuperscript{21} for tinnitus-specific quality of life (TSQoL) measured as “disturbance.” One study\textsuperscript{16} found conflicting results for TSQoL (e.g., improved TSQoL or no difference compared with placebo), depending on the instrument used to measure the outcome.

The only intervention that consistently showed statistically significant effects on multiple outcomes was sertraline, which was evaluated against placebo in a 16-week study of 63 persons who had a mean age of 42 years. These persons were recruited from a specialized audiology clinic and given 50 mg/day of the active therapy or placebo. Sertraline was shown to be more efficacious than placebo in reducing loudness, improving global quality of life, and alleviating severity. Sertraline also had a greater impact on reducing depression symptoms, although the reduction failed to reach statistical significance at the 5-percent level on one of the three scales used to measure depression.

Overall, little evidence was found to suggest that the therapies led to improvements over placebo on any of these outcomes. These results are in agreement with the conclusions of previous systematic reviews, which found insufficient, inconsistent, or no evidence of treatment effects.\textsuperscript{65-70}

In terms of SOE, there is insufficient ability to assess whether the published evidence reflects true effects. Effect-size estimates were inconsistent or imprecise, and risk of bias was moderate. Furthermore, most treatments were evaluated in single studies, which may or may not represent the true effect of any particular therapy. Sample sizes tended to be small (<100 persons), and power calculations were largely absent from the published reports, leading to the possibility that many studies were underpowered to detect true effects. Lengths of followup were too short to assess the durability of treatment over time, and the validity and discriminative ability of many outcome measurement instruments was questionable.

**Medical Interventions**

Eleven studies evaluated four different types of medical interventions that included rTMS,\textsuperscript{29,30,32-34} electromagnetic stimulation,\textsuperscript{31} LLLT,\textsuperscript{35-37} ACRN,\textsuperscript{39} and acupuncture.\textsuperscript{38} Almost all studies in this group evaluated TSQoL. In general, SOE for TSQoL is rated as insufficient based on the high risk of bias, and the small sample sizes, lack of power calculations, and lack of specification of the primary outcomes are factors related to the imprecise rating. Many of the studies did not show statistical differences between groups, but limited statistical power is likely an important factor. A clear trend for harms was difficult to specify across the differing interventions. The relative potential for long-term harms could not be evaluated in the short-term treatment trials included in this group.

When considering the individual types of interventions and efficacy with respect to TSQoL, the studies consistently showed no significant difference between treatment and inactive comparators. For rTMS and electromagnetic stimulation, the evidence was rated as insufficient. There was some evidence that longer term effects (improvement in TSQoL scores) occurred with low-frequency rTMS (1 Hz) at up to 6 months followup,\textsuperscript{29} but this single study had high risk of bias. Our review also showed that adverse effects were generally poorly evaluated and reported. A previous systematic review\textsuperscript{71} reached similar conclusions, suggesting that the evidence of benefit for rTMS is limited, and also noted the lack of long-term monitoring within the studies with respect to safety.

With respect to the interventions of ACRN, LLLT, and acupuncture, SOE was rated as insufficient for TSQoL. Only five trials evaluated the outcome of perceived loudness,\textsuperscript{32,35,36,38,39} and most trials showed no statistical differences between treatment and inactive control groups; however, the studies had small sample sizes and high risk of bias. SOE was rated as insufficient. One intervention (ACRN) showed small differences for one stimulation parameter compared with sham stimulation.\textsuperscript{39} However, due to the added problem of the diversity of the medical interventions that evaluated this outcome, we rate the SOE as insufficient for all of these interventions.

A single study examining LLLT relative to sham LLLT evaluated an outcome capturing anxiety symptoms and depression symptoms,\textsuperscript{36} and was judged to have insufficient SOE. No studies evaluated the effect of these interventions on sleep disturbance and global quality of life.

Future research should provide a more coherent rationale for the particular treatment approaches based on current neurological science principles, including justification for the dose of the intervention.

**Sound Technology Interventions**

Four unique RCTs\textsuperscript{40-43} and a related study\textsuperscript{44} were eligible for this intervention category. Two of the studies\textsuperscript{41,44} evaluated the relative effectiveness of various sound-based interventions to determine whether benefits were enhanced when sound generators were combined with CBT, information, or relaxation therapies. Half of the studies reported some benefits from sound generation, but none demonstrated any statistically significant differences.
relative to comparator therapies. Two recent systematic
reviews that evaluated different sets of eligible studies
found similar results. The authors of these reviews
discussed the diversity of interventions in this domain
and felt the evidence was insufficient to draw conclusions
about the effectiveness of any therapies.

Psychological and Behavioral Interventions

Similar to the medical interventions, the psychological and
behavioral interventions were diverse, thereby preventing
a clear overall summary of effects. Even the studies
with similar interventions had marked differences in the
focus and administration of therapy, which enhanced the
difficulty of making between-study comparisons. Despite
this diversity, the overall SOE was low that CBT and
coping approaches showed an improvement in TSQoL,
suggesting some confidence that the studies evaluating
these interventions reflect true effects.

Behavioral interventions (i.e., relaxation, education, TRT)
employed an isolated approach that did not confer the same
degree of benefit and were rated as having insufficient
SOE, being plagued with the same problems as the studies
evaluating pharmacological and medical interventions.

CBT combined with other behavioral interventions
were common treatment options. The development of
progressive or staged treatments is an active area of
interest in the tinnitus field, and this may be a promising
avenue for further exploration in future studies. However,
trials evaluating complex interventions are problematic if a
simple parallel design is employed. Factorial designs will
assist in disentangling the relative benefits of the different
components of multimodal interventions.

Adverse effects were largely not reported for psychological
and behavioral interventions. Some studies reported an
absence of adverse effects, but in one study, some patients
reported that the self-monitoring of the loudness and
discomfort caused by their tinnitus resulted in a worsening
of symptoms.

Future Research Recommendations

Key Question 1

- Develop studies to evaluate the comparative
effectiveness of instruments used to assess the severity
and status of subjective idiopathic tinnitus.

Key Question 2

Population

- Include a broader spectrum of adult patients with
respect to age, sex (equal proportion of men), and
ethnicity (broader representation of ethnic groups).
- Include patients recruited from primary care settings.
- Capture detailed information about prior treatments
and ensure that future studies do not sample only
from subjects for whom previous treatments were not
effective.
- Specify patient medical histories more clearly.
- Collect information on the use of concomitant
interventions.

Comparator and Study Design

- Enroll sufficient samples to show clinically important
differences between treatment groups, justify minimum
clinically important differences, and justify sample
sizes.
- Enroll sample sizes large enough to evaluate
confounders.
- Utilize Phase II trials to establish therapeutic doses and
preliminary effect sizes to inform the design of Phase
III RCTs.
- Have a length of followup that is long enough to study
medium- to long-term outcomes.

Intervention

- Explain the dosing rationale for off-label medications.
- Collect information on concomitant medications.
- Specify the training and experience of the person(s)
delivering the interventions.

Outcomes

- Identify outcomes as primary or secondary.
- Use scales with established psychometric properties
in populations with subjective idiopathic tinnitus to
measure patient-reported outcomes.
- Assess the responsiveness to change of outcome
measurement instruments (e.g., visual analog scale) in
persons with tinnitus.
- Back-translate scales prior to use in languages other
than the language in which they were developed.
• Measure global quality of life to capture how persons value the risk-benefit tradeoff between efficacy and adverse effects.
• Use the Consolidated Standards of Reporting Trials (CONSORT) guidelines for reporting adverse effects (harms).

Other
• Report RCT results in conformity with CONSORT.
• Register study protocols in clinical trial registries and update trial information in these registries regularly.

Key Question 3
• Develop studies to evaluate the natural history and prognostic factors in persons with subjective idiopathic tinnitus.
